Abstract. Information about past climate, tectonics, and landscape evolution is often obtained by dating geomorphic surfaces comprising deposited or aggraded material, e.g. fluvial fill terraces, alluvial fans, volcanic flows, or glacial till. Although surface ages can provide valuable information about these landforms, they can only constrain the period of active deposition of surface material, which may span a significant period of time in the case of alluvial landforms. In contrast, surface abandonment often occurs abruptly and coincides with important events like drainage reorganization, climate change, or landscape uplift. However, abandonment cannot be directly dated because it represents a cessation in the deposition of dateable material. In this study, we present a new approach to inferring when a surface was likely abandoned using exposure ages derived from in situ-produced cosmogenic nuclides. We use artificial data to measure the discrepancy between the youngest age randomly obtained from a surface and the true timing of surface abandonment. Our analyses simulate surface dating scenarios with variable durations of surface formation and variable numbers of exposure ages from sampled boulders. From our artificial data, we derive a set of probabilistic equations and a MATLAB tool that can be applied to a set of real sampled surface ages to estimate the probable period of time within which abandonment is likely to have occurred. Our new approach to constraining surface abandonment has applications for geomorphological studies that relate surface ages to tectonic deformation, past climate, or the rates of surface processes.

1 Introduction

Geomorphological studies that link the formation of landforms to past changes in climate or tectonic deformation depend on the accurate dating of surfaces comprising aggraded or deposited material. Surfaces commonly targeted for dating include alluvial fans, fluvial fill terraces, glacial till, pediments, and volcanic flows, among others. For example, the ages of fluvial fill terraces and alluvial-fan surfaces have been used to (i) decipher how erosion and sedimentation have responded to past hydroclimate changes (Owen et al., 2014; Schildgen et al., 2016; Tofelde et al., 2017); (ii) derive time-integrated slip rates for active faults (e.g. Frankel et al., 2007, 2011; Gosse, 2011; Hughes et al., 2018); and (iii) quantify the rates of surface processes such as weathering, landform erosion, or channel avulsion and incision (Schildgen et al., 2012; Regmi et al., 2014; Bufe et al., 2017; D’Arcy et al., 2018).

A common assumption is that a geomorphic surface can be represented by a single formation age. Surfaces are usually point-sampled and dated in multiple locations, e.g. by cosmogenic nuclide exposure dating of surface boulders. Typically, sampling is limited to a small number of (often fewer than 10) large, stable surface boulders, which exhibit no evidence of weathering, rotation, or disturbance. From the set of exposure ages obtained, an average surface age can be calculated with an uncertainty that reflects both analytical uncer-
tainty and the spread of sampled ages. However, many geomorphic surfaces are active for an extended period of time, during which material is continually deposited until the surface is abandoned (e.g. Savi et al., 2016; Denn et al., 2017; Foster et al., 2017). Alluvial-fan surfaces provide one example. Rather than being formed instantaneously, fan surfaces are typically active for thousands or tens of thousands of years before being abandoned when the channel avulses or incises (e.g. Dühnforth et al., 2007). This prolonged period of activity results in a meaningful spread in ages collected from a single surface (e.g. Owen et al., 2011). For any geomorphic surface with a non-negligible period of formation, a set of surface ages will capture a portion of the full time span over which that surface was active. An average of those ages will sit somewhere within the true time span of surface deposition, whereas the maximum age might approximate the onset of surface activity, and the minimum age might approximate the timing of surface abandonment.

In some cases, the timing of surface abandonment may be a more useful constraint than an average surface age. In contrast to surface deposition, abandonment occurs at a particular moment in time (e.g. coinciding with a switch to incision) and so can, in principle, be defined with greater precision. For surfaces with an extended period of formation, the timing of abandonment is more likely to coincide with events of interest such as reorganization of a drainage network (Bufe et al., 2017); changes in climate, sediment supply, or base level (Steffen et al., 2009; Tofelde et al., 2017; Mouslopoulou et al., 2017; Brooke et al., 2018); or tectonic deformation such as faulting, uplift, or subsidence (e.g. Frankel et al., 2007, 2011; Ganev et al., 2010). Abandonment ages would also benefit any study that uses surface exposure dating to measure the rates of post-depositional processes, such as in situ weathering (e.g. White et al., 1996, 2005; D’Arcy et al., 2015, 2018), the topographic decay of landforms (e.g. Hanks et al., 1984; Andrews and Bucknam, 1987; Spelz et al., 2008), or channel avulsion and incision (e.g. Schildgen et al., 2012; Finnegan et al., 2014; Malatesta et al., 2017). Yet the abandonment of a surface represents a cessation in the deposition of dateable material, and therefore cannot be directly dated. Instead, the timing of abandonment must be inferred. Some studies make assumptions about when geomorphic surfaces were abandoned based on independent information such as palaeoclimate records (e.g. Macklin et al., 2002; Cesta and Ward, 2016); others assume that the youngest sampled surface ages fall close to the timing of surface abandonment (e.g. Sarkanay et al., 2015; Foster et al., 2017; Ratnayaka et al., 2018; Clow et al., 2019). These assumptions risk interpretations that are circular (in the former case) or potentially inaccurate (in the latter case), highlighting the need for a robust method to quantitatively infer the timing of surface abandonment from a set of sampled surface ages.

Here, we introduce a new probabilistic approach to constraining when a depositional surface was abandoned based on what is known about its activity. We use artificial data to randomly point-sample the ages of virtual surfaces in scenarios that are representative of studies dating natural geomorphic landforms such as alluvial fans. We quantify how close the youngest obtained age is likely to fall within the true timing of abandonment, depending on the overall period of surface activity and the number of samples collected. From these artificial data, we derive a set of probabilistic equations and a MATLAB tool that can be applied to real geomorphic surfaces to estimate when they were abandoned. Finally, we demonstrate the application of these equations and the MATLAB tool to natural surfaces with a case study of dated alluvial-fan surfaces in Baja California, Mexico.

2 Justification

Here, we present a hypothetical example of a dated alluvial-fan surface to illustrate why the timing of abandonment may, in some cases, be more useful than an average of sampled surface ages. Consider an alluvial-fan surface that was active for a 30 kyr time span, starting at 80 ka and ending at 50 ka, when the surface was abandoned due to fan incision (Fig. 1). In this example, deposition occurred on the fan surface throughout a period of climatic stability and abandoned when the climate changed, and we make the assumption that there is an equal likelihood of obtaining any age within the entire period of deposition. A distribution of surface ages can be obtained by point-sampling the fan surface; an approach analogous to studies that measure the exposure ages of boulders atop landforms. We present two arbitrarily selected possible outcomes in Fig. 1, where six surface ages are obtained. In scenario 1, the ages are distributed relatively evenly through time, producing a mean age of 65.8 ka, which closely approximates the true average surface age of 65 ka, with a standard deviation of 10.5 kyr. In scenario 2, the ages obtained are unevenly distributed through time, producing a slightly older mean surface age (71.4 ka) and a smaller standard deviation (5.2 kyr). These scenarios are plotted against time in Fig. 1b as data points and kernel density plots, and they resemble equivalent natural datasets (e.g. Owen et al., 2014).

Sample set 2 is more tightly clustered than sample set 1, despite being less representative of the average surface age, illustrating that greater clustering of ages is not necessarily an indicator of accuracy. Furthermore, neither average age corresponds to any meaningful event. The fan surface was equally active for the entire period between 80 and 50 ka, the average ages sit within a period of climatic and depositional stability, and the peaks in the kernel density plots are artefacts created by randomly sampling a linear series.

In contrast, the abandonment of the fan surface does occur at a precise moment in time when deposition ends at 50 ka. In this example, abandonment coincides with an abrupt change in climate that triggered an incision event (cf., Simpson and...
Figure 1. (a) Conceptual alluvial-fan surface that was formed over a 30 kyr period, from 80 to 50 ka, after which it was abandoned, e.g. due to incision. Two different dating scenarios (sample sets 1 and 2) are shown in which six surface ages are randomly selected. (b) The true period of surface activity (grey bar) compared with the sampled ages presented as data points (circles), kernel density plots, and mean surface ages ± 1 standard deviation (stars). A hypothetical climate scenario is depicted as a dotted line.

Castelltort, 2012), so it is arguably a more informative target for dating than an average age that imprecisely approximates the mid-point in the duration of surface deposition. However, the abandonment of the surface represents a cessation in the deposition of dateable material, so its timing instead must be inferred from what is known about the surface activity. Given that (i) the sampled ages constrain the time span over which the surface was formed and (ii) abandonment occurred sometime after the youngest age, it could be assumed that the youngest sampled age best approximates abandonment. In scenario 1, the youngest age falls within ~1 kyr of surface abandonment, which would enable a correct interpretation of correlation between fan incision and the climate change event. In scenario 2, however, there is a ~14 kyr discrepancy between the youngest sampled age and the timing of surface abandonment, which would probably fail to demonstrate the correlation between climate change and fan incision. Therefore, the question becomes the following: how close is the youngest age obtained from a surface to the actual timing of surface abandonment?

This question cannot currently be answered for a natural dataset, yet the ability to reliably estimate when a surface was abandoned has important implications for many geomorphological applications (see Sect. 1). In this study, we use artificial data to simulate natural surfaces that undergo active deposition over variable periods of time and dated with a limited number of surface ages. These artificial data are analogous to studies that date natural geomorphic surfaces, for example, with cosmogenic nuclide exposure ages obtained from sampled boulders on alluvial fans or fluvial fill terraces. However, unlike field-based datasets, artificial data enable us to constrain the time difference between the youngest age obtained from a geomorphic surface and the true timing of surface abandonment, which is generally unknowable for natural surfaces. There are several additional advantages to taking an artificial-data approach. First, we can repeat the random sampling of surface ages (e.g. as depicted in Fig. 1) many times to probabilistically determine where the youngest sampled age tends to fall with respect to abandonment. Second, we can prescribe the surface parameters, meaning the exact timing of abandonment and the full period of surface activity are known. Third, we can select surface properties that are representative of natural geomorphic surfaces and numbers of samples commonly obtained in geomorphic studies. Fourth, we can perform a thorough quantification of the uncertainties in our analyses. For the above reasons, the artificial-data approach allows us to derive a set of equations and develop a MATLAB tool that can then be applied to natural datasets (a set of surface ages) to determine the probability of surface abandonment occurring within a specified window of time.

3 Methods

3.1 Artificial-data approach

We used artificial data to constrain the temporal discrepancy, which we denote \( \tau \), between the youngest age sampled on a surface (\( a_{\text{min}} \)) and the actual timing of surface abandonment (\( t_{\text{aban}} \)):

\[
\tau = a_{\text{min}} - t_{\text{aban}}.
\]  

(1)

Our experiments are designed to be representative of natural alluvial-fan surfaces but the results are more widely appli-
Our artificial-data experiments simulate surfaces with durations of activity, \( T \), between 10 and 50 kyr, sampled with numbers of surface ages, \( n \), between 2 and 10. These values are representative of natural alluvial-fan surfaces and typical dating studies involving a small number of ages. For each combination of \( T \) and \( n \), we randomly sampled a set of surface ages 10,000 times, allowing us to constrain the probability that \( a_{\text{min}} \) falls within a certain temporal window (\( \tau \)) of \( t_{\text{aban}} \) in each scenario.

3.2 Implementation

We first implemented our experiments using discrete sampling within a spreadsheet. For each surface, we created a list of selectable surface ages spanning the total period of surface activity, \( T \), and placed at equal intervals of 0.1 kyr. For the example case (Fig. 1), this would mean a list of selectable ages of 80.0, 79.9, 79.8 ka, etc., to a minimum value of 50.0 ka. We chose periods of surface activity, \( T \), equal to 10, 20, 30, 40, and 50 kyr. From each list, we randomly selected \( n \) unique values and repeated this exercise 10,000 times for each integer value of \( n \) between 2 and 10. For example, if \( n = 6 \) and \( T = 20 \) kyr, then we extracted 10,000 different datasets, each comprising six randomly selected ages, from the 20 kyr long list of selectable ages available at 0.1 kyr intervals. This process is analogous to random sampling of six boulders for cosmogenic nuclide exposure dating on an alluvial-fan surface that formed over a 20 kyr period and deposited a selectable boulder once every 100 years. We extracted 10,000 sets of ages for each of the 45 different combinations of \( T \) (five unique values) and \( n \) (nine unique values). For each dataset, we calculated the mean value of the selected ages, \( \bar{a} \), and the time difference between the youngest age and the abandonment time, \( \tau \). We then determined cumulative frequency distributions of \( \tau \) in each scenario with a given combination of \( T \) and \( n \).

To test whether 10,000 iterations are sufficient to produce reliable statistics and whether the discretization of ages has an important effect, we repeated all our artificial-data experiments using a non-discrete approach in a MATLAB script. We defined \( T \) as a time range, from within which any point in time could be randomly sampled, i.e. tens of thousands of “selectable” surface ages were available rather than hundreds of discrete values. Performing 100,000 iterations with the MATLAB script produced results that are indistinguishable from the discrete spreadsheet-based approach with 10,000 iterations. All data analyses are provided by D’Arcy et al. (2019) in an online data repository. Finally, we explore the assumptions and limitations of our analyses in Sect. 5.3.

3.3 Experimental assumptions

In designing our artificial-data experiments, we make several assumptions. First, surface ages are randomly selected from the total period of surface activity. Therefore, when
constructing our experiments, we assume that when ages are obtained from real geomorphic surfaces, they are randomly point-sampling the full time span of surface formation, and that this time span represents a uniform probability distribution of selectable ages. A uniform probability of ages may not be realistic in certain natural cases, for example, if boulders on an alluvial-fan surface are spatially clustered by age and all samples are taken from one part of the surface. Second, the entire period of surface activity is assumed to be available for sampling, i.e. no subset of the surface history is missing as a result of processes like burial or erosion. Third, all selectable ages within the period of surface activity have an equal likelihood of being sampled; this implies that the surface formed with a constant deposition rate and there are no pulses of activity that increase the probability of sampling a particular age. Finally, we do not explicitly factor in processes like nuclide inheritance, erosion, or incomplete exposure, which can affect exposure ages derived from cosmogenic nuclides. We consider the implications of all these assumptions for natural datasets in Sect. 5.3.

4 Results

4.1 Random sampling of surface ages

To illustrate the results of our experiments, we first present one artificial-data scenario in Fig. 3 in which the surface is formed between 80 and 50 ka (i.e. $T = 30$ kyr) and is randomly sampled with $n = 2, 4, 6,$ or 8 ages (with 10 000 repeat experiments for each value of $n$). Figure 3a shows how a frequency distribution of the mean value of all sampled ages, $\bar{a}$, changes with $n$. The distribution is centred on the true average surface age of 65 ka and narrows as a greater number of ages are sampled. If only two ages are sampled, then $\bar{a}$ can occupy almost any age within the full period of surface activity. As $n$ increases, $\bar{a}$ tends to fall closer to 65 ka. The distribution of $\bar{a}$ approaches a normal distribution as $n$ increases. This observation is compatible with the central limit theorem and the law of large numbers: $\bar{a}$ converges on the true average surface age as the number of samples increases, despite the dataset randomly sampling a linear series.

A frequency distribution can also be plotted for the youngest age, $a_{\text{min}}$, randomly selected from the surface (Fig. 3b). If only two ages are obtained, then the youngest can fall almost anywhere between 50 and 80 ka, although the distribution is asymmetric and younger values of $a_{\text{min}}$ occur slightly more frequently than older values. As $n$ increases, the distribution of $a_{\text{min}}$ shifts towards 50 ka such that when $n = 8$, $a_{\text{min}}$ falls within 5–10 kyr of $t_{\text{abandon}}$ (i.e. $\tau$ is equal to 5–10 kyr) in the majority of sampling experiments. Cumulative frequency distributions of $\tau$ reveal how close the youngest sampled age comes to the known timing of surface abandonment (Fig. 3c). For example, if only two ages are obtained, then in 60% of experiments, $\tau \leq 12$ kyr, i.e. the youngest
age falls somewhere within 12 kyr of abandonment. If six ages are obtained, then in 90% of experiments, $\tau \leq 10$ kyr. Any percentile of $\tau$ can be measured from Fig. 3c, allowing $\tau$ to be plotted against $n$ (Fig. 3d). As a greater number of ages are obtained, the value of $\tau$ associated with a given percentile decreases, i.e., the youngest sampled age comes closer to the timing of surface abandonment. However, the decrease in $\tau$ is non-linear and diminishes with increasing $n$. For example, as $n$ increases from two to four ages, the 95th percentile of $\tau$ falls from ~23 to ~16 kyr, but collecting another two ages ($n = 6$) only reduces $\tau$ to ~12 kyr. The 95th percentile of $\tau$ falls below 10 kyr when $n$ exceeds seven ages. In other words, if seven ages are randomly sampled from a surface, abandonment will have occurred within 10 kyr after the youngest age in 95% of cases.

We equate the percentiles of $\tau$ in Fig. 3c with the probability, $P$, of abandonment occurring within a time window defined by $\tau$. Thus, if $P = 0.9$, the window of time $\tau$ (placed immediately after $a_{\text{min}}$) is large enough that in 90% of our experiments, the true timing of surface abandonment would fall within it. This is equal to the 90th percentile of $\tau$, which would be 7.5 kyr for the scenario $T = 30$ kyr and $n = 8$, for example (Fig. 3d). Note that in this scenario, $\tau$ does not imply that the surface was abandoned exactly 7.5 kyr after $a_{\text{min}}$, but rather that there is a 90% likelihood that abandonment occurred anywhere within a 7.5 kyr window after $a_{\text{min}}$. The probable window of abandonment, $\tau$, increases with $P$ because a larger window of time is required to capture the true timing of abandonment in a greater proportion of cases.

At the same time, $\tau$ is inversely and non-linearly related to the sample size of ages obtained, $n$ (Fig. 4). The dependencies between $\tau$ and $n$, $T$, and $P$ are illustrated in Fig. 4 for all tested scenarios that are representative of natural alluvial-fan surfaces ($n = 2$ to 10; $T = 10$ to 50 kyr), with probabilities between 0.50 and 0.95. For example, if six ages are obtained from a surface that formed over a 30 kyr duration, then $\tau = 12$ kyr for $P = 0.95$ (Fig. 4a). In other words, in 95% of cases the youngest of six ages obtained from such a surface will fall within 12 kyr of the true timing of abandonment. Only in 5% of cases does the discrepancy between $a_{\text{min}}$ and abandonment exceed 12 kyr. If $P$ decreases to 0.5 (Fig. 4f), then $\tau$ decreases to 3 kyr for this particular scenario ($n = 6$ and $T = 30$ kyr).

The results of our artificial-data experiments (Fig. 4) can be described by one equation that allows $\tau$ to be calculated for any scenario:

$$\tau = \tau_0 + PTe^{kn}.$$  (2)
Here, the parameter \( k \) is a decay constant with a negative value that increases exponentially with \( P \) (Fig. 5a):

\[
k = a + be^{cP}.
\]

Constants \( a \), \( b \), and \( c \) can be derived empirically using our artificial data. Note that we calibrate all our equations with time in kiloyears (kyr).

\[
a = -0.425 \pm 0.029, \quad b = 0.011 \pm 0.011, \quad c = 2.830 \pm 0.885
\]

The parameter \( \tau_0 \) increases linearly with \( T \), but with a slope that increases exponentially with \( P \) (Fig. 5b), and can therefore be described by a pair of relationships:

\[
\tau_0 = mT, \quad m = m_0 + ge^{hP}.
\]

Parameters \( m_0 \), \( g \), and \( h \) are constants with values again determined empirically from our artificial-data experiments:

\[
m_0 = 0.019 \pm 0.008, \quad g = 0.005 \pm 0.002, \quad h = 3.784 \pm 0.406.
\]

Given that \( \tau_0 \) signifies the value of \( \tau \) as \( n \) tends towards infinity, it represents the limit of precision that can be obtained on the abandonment period, \( \tau \), when inferring the timing of surface abandonment with this probabilistic method. For the scenarios shown in Fig. 5b, which represent reasonable values of \( T \) for natural alluvial fans and desirable values of \( P \), \( \tau_0 \) varies from a few centuries to \( \sim 10 \) kyr.

### 4.2 Total period of surface formation

Equation (2) can be solved for \( \tau \) (using the parameterization of Eqs. 3 through 5) with knowledge of only the number of ages sampled, \( n \), and the total period of surface formation, \( T \), as well as a chosen probability, \( P \). We are able to parameterize \( \tau \) using artificial data because we know the value of \( T \) in our experiments. However, when sampling natural depositional surfaces, \( T \) is unknown and instead only the span of sampled ages, \( a_{\text{max}} - a_{\text{min}} \), can be measured. This span might approximate \( T \), but some fraction of time will not be captured. Fortunately, our artificial-data experiments also allow us to determine what fraction of \( T \) is captured by \( a_{\text{max}} - a_{\text{min}} \) in scenarios of varying \( n \) (Fig. 6).

The artificial data indicate that, for example, six randomly distributed ages will span \( \sim 70 \% \) of the total time span of surface activity, \( T \), in the average case. In the 1 \% of worst (most clustered age) cases, \( a_{\text{max}} - a_{\text{min}} \) will only represent \( \sim 30 \% \) of \( T \), and in the 1 \% of best (least clustered age) cases it will represent more than 95 \% of \( T \). In half of all experiments for \( n = 6 \) (from P25 to P75), \( a_{\text{max}} - a_{\text{min}} \) falls within 60 \%–85 \% of \( T \). There is a diminishing improvement with an increasing number of sampled ages, such that by \( n = 10 \) the average span of ages has only increased to \( \sim 80 \% \) of \( T \) and 50 \% of all experiments fall between 75 \% and 90 \% of \( T \). An order of magnitude more ages (hundreds) would be needed for the mean \( a_{\text{max}} - a_{\text{min}} \) to come within 95 \% of the full period of surface activity.
A regression can be fitted to the distributions in Fig. 6, taking the form
\[
a_{\text{max}} - a_{\text{min}} \over T = q + re^{|n|}. \tag{6}
\]
Parameters \(q\), \(r\), and \(s\) are empirical coefficients derived graphically from our artificial data. For the mean case (the solid black line in Fig. 6), they take the values
\[
q_{\text{av}} = 0.838 \pm 0.007, \\
r_{\text{av}} = -1.035 \pm 0.030, \\
s_{\text{av}} = -0.366 \pm 0.016.
\]
Equation (6) is also fitted to \(\pm 1\) standard deviation (\(\sigma\)) above and below the mean values in Fig. 6 (dashed black lines). For \(1\sigma\) above the mean, parameters \(q\), \(r\), and \(s\) take the values
\[
q_{+1\sigma} = 0.928 \pm 0.005, \\
r_{+1\sigma} = -0.983 \pm 0.055, \\
s_{+1\sigma} = -0.512 \pm 0.027.
\]
For \(1\sigma\) below the mean, parameters \(q\), \(r\), and \(s\) take the values
\[
q_{-1\sigma} = 0.764 \pm 0.007, \\
r_{-1\sigma} = -1.196 \pm 0.015, \\
s_{-1\sigma} = -0.296 \pm 0.008.
\]
Equation (6) can therefore be used to estimate the size of \(T\) in the average case \(\pm 1\sigma\) bounds, given the measured span of ages collected from a surface. Equations (2) through (6) are thus calibrated using our artificial data, and can be used to probabilistically calculate the window of time during which any dated surface was likely abandoned.

4.3 Application to measured surface ages

Given that Eqs. (2) through (6) are probabilistic (i.e. \(P\) is a variable), our artificial-data approach can be used to infer a probability distribution of abandonment ages from a set of measured surface ages. We illustrate the steps involved in applying Eqs. (2) through (6) and the MATLAB script to real data in Fig. 7.

To solve for \(\tau\) at a discrete probability value (\(P\)), \(T\) is first calculated with Eq. (6) and \(r\) is then calculated using Eq. (2), with parameters defined in Eqs. (3) through (5) (Fig. 7a). These discrete values of \(\tau\) can be converted into a probability distribution by calculating the density of \(P\) within fixed increments of \(\tau\). For example, in Fig. 7a, 50% of the probability of abandonment falls within a relatively small window of time (the light blue bar for \(P = 0.5\)), whereas a longer window of time is required to contain an additional 45% of the probability of abandonment (the light pink bar for \(P = 0.95\)). Thus, the density of \(P\) is greater within the window \(\tau\) for \(P = 0.5\), and this density diminishes as \(\tau\) and \(P\) increase. The MATLAB script (provided in the Supplement) enables determination of the continuous probability distribution of \(\tau\). After generating artificial data based on \(n\) ages and a duration of deposition \(T\) (from Eq. 6), the script calculates the density of \(P\) within fixed increments of \(\tau\). If the sampled surface ages are known with exact precision, then the resulting distribution of \(\tau\) values provides a probability distribution of times that directly postdate the youngest age and yield a probability distribution of surface-abandonment ages (Fig. 7a).

However, real surface ages have associated uncertainties that must also be incorporated into the estimated abandonment ages (Fig. 7b). The MATLAB tool is designed to incorporate this uncertainty, and is explained in the following steps. First, we use \(\pm 3\sigma\) uncertainty in \(a_{\text{min}}\) to characterize the probability distribution of potential \(a_{\text{min}}\) values. In the example schematic (Fig. 7b) we assumed a normal distribution, as is typical for exposure ages of individual boulders, but alternative distributions could be used. This distribution of \(a_{\text{min}}\) values is then discretized, and separate probability distributions of \(\tau\) are calculated for each potential value of \(a_{\text{min}}\), i.e. repeating Fig. 7a. The resulting, temporally shifted probability distributions of \(\tau\) are weighted according to the probability distribution of \(a_{\text{min}}\) and summed, producing an overall probability distribution of likely abandonment ages that accounts for uncertainty in the youngest age (Fig. 7c). If the uncertainty in \(a_{\text{min}}\) is small compared to \(\tau\) calculated using Eq. (2), then incorporating age uncertainty will have little impact on the resulting probability distribution of abandonment ages. If the uncertainty on \(a_{\text{min}}\) is large, it will have a greater influence on the final probability distribution of abandonment ages.
Our artificial data provide new information about what measured ages represent when collected from aggraded surfaces that formed over non-negligible time spans. Crucially, our findings indicate that averages of sampled surface ages are likely to be imprecise representations of the mid-point of surface formation, which may not coincide with an external forcing event (Fig. 1). In contrast, surface abandonment typically occurs at a discrete moment in time and is more likely to coincide with external forcing events such as changes in climate or tectonics. By using artificial data, we have derived a set of probabilistic equations for inferring when a surface was likely to have been abandoned, based on a distribution of randomly sampled surface ages. These equations can complement and enhance interpretations based on any dataset comprising surface ages. The spreadsheet and the MATLAB tool allow for quantification of the full probability distribution of \( \tau \) and the MATLAB tool additionally allows for the incorporation of uncertainty in the youngest age, \( a_{\text{min}} \).

While a distribution of ages is required for dating surfaces that have formed over extended periods of time, our analyses reveal that an increasing number of ages yield diminishing returns for constraining the timing of abandonment (Figs. 3d and 4) and the total duration of surface activity (Fig. 6). An appropriate number of surface ages will depend on the desired precision, but our results indicate that there is little to be gained by obtaining more than six to seven ages per surface (Figs. 3, 4, and 6), assuming no outliers, for the purposes of most geomorphological studies. To obtain substantially more information about a surface, an order of magnitude more ages would be required. As explained in Sect. 4.1, \( \tau_0 \) represents the maximum precision with which the abandonment age can, in principle, be inferred. For many natural surfaces, \( \tau_0 \) can range from a few centuries to \( \sim 10 \) kyr (Fig. 5b), depending on the period of surface activity and the desired probability. Our methodology thus provides a new way to quantify how precisely a distribution of surface ages can be interpreted. This limit to precision should be considered in addition to the age uncertainty associated with cosmogenic nuclide exposure dating; both are important considerations when inverting landforms and sedimentary deposits for palaeo-environmental information (Foreman and Straub, 2017).

When sampling in the field, it may be advantageous to target different parts of an aggraded surface to capture as much of its period of activity as possible. This strategy applies to surfaces upon which the locus of deposition has systematically migrated during deposition. For example, if channel migration on an alluvial-fan surface resulted in a portion of its overall history being recorded in particular parts of the surface (e.g. Savi et al., 2016; Schürch et al., 2016; D’Arcy et al., 2017a, b), then greater spatial coverage would capture a greater range of ages. However, if each deposition event followed a random trajectory on the surface, resulting in all potentially selectable ages being spatially mixed, then it would be unnecessary to distribute sampling locations across the surface.

### Case study: alluvial fans in the Laguna Salada Basin, Mexico

Here, we use a case study of alluvial-fan surfaces in the Laguna Salada Basin, Mexico, to demonstrate how our findings...
can be applied to real surfaces to gain new information about when they were abandoned.

The Laguna Salada Basin is a half-graben in northern Baja California, Mexico. This basin contains well preserved alluvial fans eroded from the neighbouring Sierra El Mayor and Sierra de Los Cucapah, with at least eight generations of distinct fan surfaces formed by a sequence of aggradation and incision cycles. The ages of two of these fan surfaces – mapped as Q4 and Q7 – were estimated by Spelz et al. (2008) using $^{10}\text{Be}$ exposure ages of stable surface boulders with no evidence of erosion or disturbance (Fig. 8). We used the CREp calculator (Martin et al., 2017) to update the exposure age estimates of Spelz et al. (2008) using the time-corrected Lal/Stone scaling scheme (Lal, 1991; Stone, 2000), the ERA40 atmosphere model (Uppala et al., 2005), the atmospheric $^{10}\text{Be}$-based virtual dipole moment (VDM) geomagnetic database of Muscheler et al. (2005) and Valet et al. (2005), and the current global reference sea level high latitude (SLHL) $^{10}\text{Be}$ production rate of $4.13\pm0.20\text{g}^{-1}\text{yr}^{-1}$ in the ICE-D database (Martin et al., 2017). We assume a sample density of $2.7\text{g cm}^{-3}$ and no boulder erosion. The oldest age measured on the Q4 surface was excluded as an outlier by Spelz et al. (2008), and we maintain this interpretation. The remaining exposure ages span from $14.4\pm1.1$ to $32.1\pm2.9\text{ka}$ for Q4 ($n=5$) and $188.6\pm22.7$ to $246.9\pm13.7\text{ka}$ for Q7 ($n=6$) (Fig. 8b, yellow bars). On both fan surfaces, the dispersion of ages greatly exceeds the age uncertainty, suggesting that each surface was deposited over an extended period of time.

For both distributions of fan surface ages, we used Eqs. (2) through (6) to calculate probable abandonment windows, $\tau$, for different values of $P$. For example, on the Q4 fan surface with an $a_{\text{min}}$ of $14.4\pm1.1\text{ka}$, $\tau = 3.3\text{kyr}$ when $P = 0.5$, suggesting a 50% probability that the surface was abandoned within $3.3\text{kyr}$ after $a_{\text{min}}$, i.e. between 14.4 and 11.1 ka. The size of $\tau$ increases with $P$, as explained in Sect. 4.1, such that $\tau = 12.0\text{kyr}$ for the Q4 surface when $P = 0.95$, i.e. the abandonment window ranges from 14.4 to 2.4 ka. The full probability distribution of $\tau$ is highly asymmetric (Fig. 8c, red dashed lines). Of course, the uncertainty in $a_{\text{min}}$ must also be accounted for. To do so, we used the MATLAB script with the required inputs – $T$ and $n$; the desired number of iterations, $a_{\text{min}}$; and the 1σ uncertainty in $a_{\text{min}}$ – to derive a continuous probability distribution of $\tau$ for each fan surface that incorporates age uncertainty (Fig. 8c, solid black lines). The probability distributions of $\tau$ incorporating age uncertainty, derived for both the Q4 and Q7 surfaces, illustrate how the likelihood of surface abandonment is distributed over time for two representative natural datasets. On the Q4 surface, the measured age uncertainty is small compared to $\tau$, so the resulting $\tau$ distribution has an asymmetric shape that is primarily determined by the form of Eq. (2) and our artificial-data calibration (Figs. 3 and 4). The majority of the Q4 $\tau$ distribution occupies a short time span that is smaller than the spread of sampled surface ages; this result supports our reasoning that the timing of surface abandonment can, in some cases, be constrained more precisely than a representative age of surface formation (see Sect. 2). The age uncertainty in $a_{\text{min}}$ is significantly larger on the older Q7 surface and therefore dominates the probability distribution of $\tau$, giving it a wider and more symmetrical shape despite the greater number of measured ages, $n$. This result underscores the importance of accounting for age uncertainty when using our equations to infer the likely timing of surface abandonment.

5.2.1 Climatic implications

Our estimates of when the Laguna Salada fans were abandoned have important climatic implications. Spelz et al. (2008) speculated that the aggradation and incision of the fan surfaces was partly controlled by past climate changes, and there is growing evidence that alluvial systems can be highly sensitive hydroclimate recorders (D’Arcy et al., 2017a, b; Terrizzano et al., 2017; Tofelde et al., 2017; Rantayuka et al., 2018; Wickert and Schilde, 2019). We explore this idea by comparing the surface age data with two palaeoclimate proxy records (Fig. 8d): the GRIP ice core $\delta^{18}\text{O}$ record from Greenland (Johnsen et al., 1997) and the LR04 global benthic $\delta^{18}\text{O}$ stack (Lisiecki and Raymo, 2005). These records primarily reflect the growth and decay of continental ice sheets, which are generalized into marine isotope stages (MIS).

The obtained Q7 ages clearly coincide with the broadly interglacial conditions of MIS 7, so we interpret that the surface was deposited throughout this stage. Our statistical analyses indicate that the Q7 surface was abandoned – in this case due to fan incision – during the subsequent MIS 6 and coinciding with a climatic transition to more glacial conditions. Indeed, 71% of the area beneath the Q7 $\tau$ distribution falls within MIS 6 (191–130 ka), which we interpret as a 71% likelihood that the surface was abandoned and incised during this stage. For the Q4 fan surface, the sampled ages alone indicate that abandonment coincided with the end of the Last Glacial Maximum (MIS 2) and the global shift to interglacial conditions in the Holocene. Spelz et al. (2008) interpreted this observation (fan incision during a shift to interglacial climate) to contradict the Q7 data (fan incision during a shift to more glacial conditions). However, supplementing the measured ages with our probabilistic analyses reveals that Q4 abandonment is likely to have occurred during the Younger Dryas, a short-lived climate episode from 12.9 to 11.7 ka during which the Northern Hemisphere climate returned to a cooler state (Carlson, 2013). We find that the peak of the $\tau$ distribution – i.e. the single most probable abandonment age – falls at 12.7 ka (Fig. 8c). This interpretation reconciles the Q7 and Q4 surfaces on the Laguna Salada fans, which would have both been incised as a result of climatic shifts towards more glacial conditions. This case study also demonstrates how our probabilistic approach, enabled by our use of artificial data, can be used to quantify the like-
The results in Fig. 8 also have tectonic implications. The Laguna Salada fans are dissected by fault scarps related to the Laguna Salada fault and the Cañada David detachment; the largest Q7 scarp has an offset of 9.9 m (Spelz et al., 2008). Typically, studies divide the fault offset by the mean surface age (which for Q7 is 215.9 ka) to estimate a time-averaged slip rate, which would be 0.046 mm yr$^{-1}$ in this example. However, as a scarp can only accumulate displacement once the surface has been abandoned, i.e. when it is no longer being resurfaced, the estimated age of abandonment may be a more appropriate timescale for determining a displacement rate. Accumulating a 9.9 m offset since 177 ka (the most likely abandonment age, Fig. 8c) would produce a time-
averaged slip rate of 0.056 mm yr\(^{-1}\) an increase of 22\%. Following this logic, the probability distribution of \(\tau\) could
be translated into a probability distribution of time-averaged slip rates. For the Q4 fan surface, calculating a slip rate with
a most likely abandonment age (e.g. 12.7 ka) instead of the
mean surface age (23.3 ka) would result in an even larger in-
crease in the calculated displacement rate of 83\%. Underes-
ting fault slip rates by this magnitude could have impor-
tant implications for tectonic and fault hazard analyses.

Spelz et al. (2008) also measured the diffusional decay of
fault scarp geometry over time, and used the calculated mean
fan surface ages to derive time-integrated scarp mass diffu-
sivities between \(\sim 0.01\) and 0.10 m\(^2\) kyr\(^{-1}\). Intriguingly, the
authors interpreted these diffusivities to be anomalously low.
More realistic values can be obtained by, again, using the es-
timated surface abandonment ages to calculate scarp mass
diffusivity, rather than average surface ages. This approach
would result in faster diffusion rates, as Spelz et al. (2008)
expected, while recognizing that a fault scarp can only form
and erode once a fan surface has been abandoned.

The alluvial fans of the Laguna Salada Basin provide a
representative example of natural, aggraded geomorphic sur-
faces that are formed over a non-negligible period of ac-
tivity and are dated with a small set of exposure ages that
randomly sample the duration of surface activity. This case
study demonstrates that our artificial-data approach can pro-
vide valuable constraints on the timing of surface abandon-
ment based on a set of exposure ages, which can improve
interpretations involving palaeoclimate, tectonics, and land-
form evolution.

5.3 Limitations to the probabilistic approach

Our artificial-data approach and the resulting parameteriza-
tion of Eqs. (2) through (6) assume that a distribution of sur-
face ages are obtained by randomly sampling the full dura-
tion of surface activity. In some cases, this assumption might
be realistic. For example, the Q7 surface on the Laguna Salada fans (Fig. 8) was sampled in different places and pro-
duced ages spanning all of MIS 7, suggesting the full dura-
tion of surface activity might be well represented. If so, our
approach could be symmetrically applied to the oldest sam-
pled age to estimate the onset of deposition. In contrast, the
Q4 surface was sampled entirely at the fan apex, where en-
hanced vertical aggradation makes it likely that the earliest
deposits from this depositional episode have been buried. In
practice, this sampling approach would improve estimates of
when abandonment occurred. By clustering the surface ages
towards the end of the depositional period, \(T\) would effec-
tively shorten, given that our approach derives \(T\) empirically
from the ages that are actually obtained from a surface, and \(\tau\)
would be constrained more precisely as a result. The total du-
ration of deposition would be biased toward younger ages by
the burial of older deposits, but this bias is unimportant when
focusing on the timing of abandonment, which is a strength
of our approach. However, vertical burial would mean that \(T\)
(solved with Eq. 6) would no longer represent the total dura-
tion of deposition, and it would therefore be inappropriate to
use our approach to estimate the onset of deposition.

Like burial, subsequent erosion of part of a surface might
hide a fragment of the period of deposition from sampling.
The implications of erosion depend on how spatially ho-
mogenous the surface is, i.e. whether erosion has randomly
eliminated selectable ages from throughout the duration of
activity or instead eradicated complete fragments of the time
span of activity. Again, erosion would only impede our
method of inferring the abandonment age if the youngest part
of the duration of activity were destroyed. Given that burial
and erosion are site specific, they cannot be universally in-
corporated into our equations and must be considered on an
individual-case basis.

Our approach assumes that all sampled surface ages are
ture ages. In reality, incorrect ages are sometimes encoun-
tered when dating surfaces. For example, cosmogenic nu-
clide exposure ages may be biased towards older ages as a
result of nuclide inheritance, as is interpreted to be the case
with the oldest exposure age on the Laguna Salada Q4 fan
surface (Fig. 8a). Including old outliers in our analyses would
lead to an over-estimation of the size of both \(T\) and \(\tau\), and
therefore unnecessarily imprecise estimates of the abandon-
ment window, but would not change the position of \(a_{\text{min}}\).
A more serious error would arise from incorrect young ages,
e.g. resulting from erosion or shielding of boulders targeted
for cosmogenic nuclide exposure dating. The inclusion of
spurious young ages could expand the apparent period of sur-
face activity \(T\) past the true timing of abandonment, leading
to estimates of \(\tau\) that are both too large and, more impor-
tantly, too young. Therefore, Eqs. (2)–(6) and the MATLAB
tool should be applied to clean datasets that do not contain
spurious ages, and particularly not spuriously young ages
when attempting to calculate abandonment times.

Finally, our approach derives the true period of surface ac-
tivity, \(T\), from the measured age range \(a_{\text{max}} - a_{\text{min}}\), based
on the results of our artificial-data experiments (see Sect. 4.2
and Fig. 6). This step is necessary because the true duration
of \(T\) is ultimately unknowable for natural surfaces, so we pa-
parameterize Eq. (6) using the mean ratio of \((a_{\text{max}} - a_{\text{min}})/T\)
among our artificial-data experiments. Of course, any given
set of real surface ages might happen to capture a greater or
smaller fraction of \(T\) than the mean case. For this rea-
son, we also provide parameterizations of Eq. (6) for \(\pm 1\)
standard deviation (\(\sigma\)) above and below the mean ratio
of \((a_{\text{max}} - a_{\text{min}})/T\), thus allowing \(\pm 1\sigma\) uncertainty in \(T\) to be
tested. In practice, the uncertainty associated with \(T\) has lit-
tle effect on the probability distributions of \(\tau\) produced by
Eq. (2), and so is likely to be insignificant for most geomor-
phological applications. To illustrate the sensitivity of \(\tau\) to
the uncertainty in \(T\), we recalculate the probability distribu-
tions of \(\tau\) for the Q4 and Q7 Laguna Salada alluvial-fan sur-
faces with the MATLAB tool (Fig. 9) using the ±1σ bounds on $T$ (Fig. 6).

The uncertainty in $T$ has a negligible effect on the probability distributions of $\tau$ for both the young and precisely dated Q4 surface where the $\tau$ distribution is most sensitive to the form of Eqs. (2) through (5), and the older, less precisely dated Q7 surface, where the $\tau$ distribution is most sensitive to the measured age uncertainty. This sensitivity analysis demonstrates how the conversion of $a_{\text{max}} - a_{\text{min}}$ to $T$ has little bearing on the estimated timings of surface abandonment. Nonetheless, our artificial-data calibration allows the ±1σ uncertainty in $T$ to be calculated, if desired.

6 Conclusions

Our study uses artificial data to simulate depositional geomorphic surfaces that form over a non-negligible time span, and are subsequently dated with exposure ages on a set of randomly sampled boulders. We investigate scenarios that are representative of natural alluvial fans, which are commonly targeted for surface dating; however, our results may be more broadly applicable to other depositional landforms that form over protracted periods of time. Our findings suggest that, for a variety of different purposes, inferring the timing of surface abandonment may provide more informative and more precise interpretations than taking an average of measured surface ages. We use our artificial data to derive a set of probabilistic equations that can be applied to a distribution of real sampled surface ages to estimate a period of time within which abandonment is likely to have occurred with a given probability. These equations account for site-specific variables including the number of ages and the duration of activity for a particular surface and our artificial-data approach can be used to generate a probability distribution of likely abandonment ages. We provide a MATLAB script that generates a probability distribution of abandonment ages for a given surface and furthermore allows for the uncertainty associated with measured ages to be incorporated. The ability to constrain the timing of surface abandonment has useful applications for geomorphological studies that relate surface ages to tectonic deformation (e.g. deriving fault slip rates), climate (e.g. reconstructing past hydroclimate changes), or the rates of surface processes (e.g. weathering and landform evolution), a subset of which we demonstrate using a case study of alluvial-fan surfaces in the Laguna Salada Basin, Mexico. The statistical framework we introduce in this paper offers a new method of probabilistically estimating when a surface was abandoned, which can complement and enhance interpretations of any distribution of sampled ages obtained from surfaces that experienced a non-negligible period of deposition.
